VEC Tutorial

Examples for the proper use of the VEC Model

Version 1.3, 29.10.2014
Status: Released by Project Group “Car Electric”

Notice: This is a printable Version of the Online Tutorials published at: http://ecad-wiki.prostep.org. The newest version can be found there.
Abstract
The VDA recommendation 4968 “Vehicle Electric Container (VEC)” defines an information model, a data dictionary, and an XML schema derived from and compliant to the model.

The intention of the model was to cover a wide range of use cases and application scenarios. For this reason the specification have to be kept generic in some degree.

To avoid dialects in VEC implementations further guidelines or recommendations are necessary. This document contributes to the unambiguous interpretation of the VEC standard. For various wiring harness definition or electrical system aspects the correct instantiation is shown.

1 Key Concepts

1.1 Parts and Documents

Figure 1: Parts and Documents

The figure above illustrates one of the most fundamental concepts of the VEC – the separation of a part and its description. In the VEC a part (PartVersion) does not contain any information about the part, except its PDM Information (PartNumber, PartVersion...). All the information about the technical properties of a part is expressed by a subclass of PartOrUsageRelatedSpecifications (e.g. a WireSpecification). The specifications itselfes are contained in a DocumentVersion.

This approach enables the VEC to address two scenarios properly:

- The description of a part is changed, but the part itself is not changed (rerelased). This can happen for example if the actual technical properties of the part stay the same, but the description is extended or corrected.
- A document and the contained specifications are describing more than one part (e.g. a drawing for a certain class of terminals). In this case it can happen that the document and the specifications are changed, but not all of the described parts have to be changed (rerelased).

1.2 Usage Nodes

Figure 2: Usage Nodes

The example illustrates the use of UsageNodes. A UsageNode represents a position in an abstract vehicle. For example the Head Light Left. UsageNodes belong to the master data and they are defined on some company wide level. They can be used to enforce consistent naming over different projects and different development streams (e.g. between geometry and electrologic).

A UsageNode can be subdivided into more detailed UsageNodes. For example the Head Light can be split up into Main Beam, Low Beam and Direction Indicator.
1.3 Physical Properties
This section describes the different methods for specifying physical properties. The following contains the different methods / types of how values can be defined.

1.3.1 Numerical Values

![Figure 3: Numerical Values](image)

1.3.2 Reference Systems

![Figure 4: Reference Systems](image)

This tutorial demonstrates how values with reference systems shall be used. In many cases (e.g. Colors) there is no single way to express a certain literal, but many different ways.

In order to correctly express such values the VEC gives the possibility to define not only the value, but the reference system in which the value is valid, too. This means if I have three valid ways to express the Color "Red", then I can define and differentiate them. If the value is defined in some standard reference system I will use this (e.g. RGB or RAL for colors). If the value is defined in some company specific reference system, this can be defined, too (see ACME Inc.). For attributes like the "baseColor" of a wire insulation it is possible to define the single value in different reference systems (in the example the...
color in RGB, RAL and company specific ACME Inc.). However all given values shall refer to the same "real" value.

2 PDM Information

2.1 Document Meta-Information

Figure 5: Document Meta-Information

All information actually defined in a VEC file is contained in a DocumentVersion. Additionally this DocumentVersion carries all the meta-information about the underlying document (e.g. for a system schematic). This information is normally shown in drawings as a title block.

The DocumentVersion contains the information about the unique naming, a multilingual description, the DocumentNumber and so on. It has subelements to define the change history (ChangeDescription), the creation and the different approvals.

2.2 Item History

Figure 6: Item History

This example demonstrates how chronological relationships between PartVersion can be established. The VEC offers two types of relationships:

1. **Derivation**: Derivation means that the successor of the relationship is a newly developed part (variant) based on an existing part.
2. **Sequence**: Sequence means that the successor is a replacement for the predecessor.

### 3 Description & Instances of Components

In the next sections some examples for the specification of parts / components are presented. In order to keep the examples as simple as possible, the described PartVersions and the containing DocumentVersions are left out. Nevertheless they are needed for a real instantiation of the VEC.

#### 3.1 Basic Component Description

![Diagram](image)

**Figure 7: Basic Component Description**

Many of the classes in the VEC are used for the definition of the general properties of a component (Part Master Data). This is done with specifications (VEC Naming Convention “*XXXSpecification*”). A specification defines all properties of a component that are that are independant of a specific usage of the component (e.g. the number of cavities of connector or the cross section area of a wire). The type of the component, and thereby the available properties, is defined by the classification of the specification (e.g. *ConnectorHousingSpecification* for a connector housing). The PDM Information of a component (e.g. the part number) is defined by a *PartVersion*.

Since a component can have properties of different classifications (e.g. a connector can also have properties of a fixing) it is possible in the VEC to define multiple different specifications for a single part. The attribute “primaryPartType” defines which the primary character of the component is.
3.2 Instantiation of Parts

If a component should be used in the VEC it must be instantiated. This can be done in two ways. The first way is used if a concrete part number is known. The second way is used if a part number is unknown and only requirements for a component should be defined.

The first case is illustrated in this diagram and is quite similar to the way how components have been used in the KBL. The part is identified by a PartVersion with a PartNumber, Version and the issuing Company. The general properties of the component are defined by a specification (a FixingSpecification in the example). The use of the component is expressed by a “PartOccurrence”. All usage specific properties of component (e.g. the length of a wire) are defined by a Role. The used role must correspond to a specification. The VEC Naming Convention is XXXRole corresponds to XXXSpecification.

In object oriented terms, one can say the PartVersion and Specification are defining the type (or classification) of a component, the PartOccurrence and the Role are defining the instance of a component.

3.3 Instantiation of Specifications without Part Number

As mentioned in the example before, there are use cases where it is necessary to define properties of component (instance), without having a concrete part number. This is quite common for example in the electrological design, where for example the cross section area of a wire is specified, but the colouring of the wire is not yet known. In
these cases the requirements for component have to be defined without having a concrete PartVersion.

For these cases, the VEC offers the concept of PartUsages. A PartUsage behaves like a PartOccurrence (it has instance specific attributes and can define Roles), but it is not necessary to reference a PartVersion. Instead it is possible to directly reference the needed specifications, which represent the requirements on the concrete component, selected later in the process.

3.4 Wires

3.4.1 Single Core Specification

The figure above illustrates the specification of a single core wire. The WireSpecification is the PartOrUsageRelatedSpecification describing the PartVersion. In order to make it possible to reuse the specification of the different WireElements (see Multi Core), the actual definition of the structure of the wire is delegated to a WireElementSpecification. The WireElement defines the context specific identification of a WireElementSpecification in the context of a specific WireSpecification (mainly needed for multi cores, but due to a consistent modeling approach also necessary for single cores). The WireElement is used for reference when a WireSpecification is instantiated (e.g. by a PartOccurrence).
3.4.2 Multi Core Illustration

This is an illustration for the multi core example that describes the specification of a multi core wire. The example uses a multi core, which is insulated with a grey insulation, shielded and which contains two FLRY cores of different colouring that are a twisted pair.

3.4.3 Multi Core Specification

The Figure displays the instantiation of the multi core wire example in the VEC. The hierarchy of the wire is highlighted in the figure in green. The specification of the brown and green FLRY core (0.35-BRGN) is actually the same as the specification in the single core example (highlighted by the red outline in the figure). It is reused and not defined redundantly. Since it is the same WireElementSpecification object, the context
specific naming of the WireElement is necessary, as mentioned in single core example (highlighted in yellow).

The only difference between the two WireElements representing the two cores is the coloring of the insulation. Therefore the two WireElementSpecifications share the same CoreSpecification, but have individual InsulationSpecifications. In the context of the displayed WireSpecification the Brown & Green Core is addressed with the identification “1”, the second Core is addressed with the identification “2”. The two Cores are grouped together by a third WireElementSpecification (2x0.35-BRGN-RTBL).

This third WireElementSpecification defines the type of grouping by a WireGroupSpecification. In the example the Grouping is the definition of a twist of the two Cores. It also defines the insulation around the two SubWireElements by an InsulationSpecification. Since the defined wire has a conductive shield as well, the described WireElementSpecification references a ShieldSpecification, too. The cross section area in the ShieldSpecification defines the nominal cross section area of the conductive material used in the shield.

### 3.5 Connectors

#### 3.5.1 Modular Connector

![Figure 13: Modular Connector](image)

This tutorial illustrates the definition / description of modular connectors. A modular connector is a connector that can be recursively assembled, so that certain fields can fitted with different other parts.
In the displayed example the PartVersion "4711" is a modular connector. The ConnectorHousingSpecification defines a regular Slot "A" with a number of cavities and a ModularSlot "B". This ModularSlot is compatible to two different inserts (defined by individual ConnectorHousingSpecifications). The two PartVersion "4712" & "4713" define these allow inserts.

3.5.2 Modular Connector Instancing

![Diagram of Modular Connector Instancing](image)

Figure 14: Modular Connector Instancing

The diagram shows the instantiation of modular connector (previous example). On the left hand side of the diagram the component description of the modular connector is shown (similar to the previous example). On the right hand side the instancing of such a modular connector is shown.

Both parts of the modular connector (the housing and the insert) have their own PartOccurrence. The ModularSlotReference defines which inserts are actually used in the specific context.

**Note:** As a wiring harness is often described in a 150% scope, it is possible that a ModularSlotReference references more than one ConnectorHousingRole as usedInserts. In these cases the variant management mechanisms have to ensure, that in a concrete case only one insert is used. This can be either done explicitly with PartStructureSpecifications or implicitly with a VariantConfiguration.
3.5.3 Connector with multiple Segment Connection Points

Figure 15: Connector with multiple Segment Connection Points

3.5.4 Instancing

The example shows a connector that has two cavity, that are only reachable through different segment connection points. By associating these SegmentConnectionPoints with corresponding PlacementPoints the SegmentConnectionPoint become ‘placeable’ on nodes in the topology of a harness.
3.6 ECU & EE Components

Figure 17: ECU & EE Components

This example illustrates how an ECU can be defined and instantiated. The left hand side shows the master data definition of the EE-Component. The right hand side of the diagram shows the usage of the EE-Component in a concrete place. An EE-Component is defined by an \texttt{EEComponentSpecification}. An EE-Component can have multiple \texttt{HousingComponents}, which can be defined more detailed with a \texttt{ConnectorHousingSpecification} (not shown in the example). These \texttt{HousingComponents} have \texttt{PinComponents} representing the different electrical pins of an EE-Component. The \texttt{PinComponent} can carry specific properties of the Pin (e.g. the Logical Signal). The physical properties of the pin can be defined by an associated \texttt{TerminalSpecification} (e.g. the maximum current for the pin). A \texttt{HousingComponent} can have multiple pins with different properties sharing the same \texttt{TerminalSpecification}.

When the EE-Component is used, it must be instantiated. In the example this is done with a \texttt{PartUsage} (no PartNumber is known for the EE-Component). For each subelement of the \texttt{EEComponentSpecification} a corresponding element is used for the instantiation. The doubled instantiation of the pin with a \texttt{PinComponentReference} and a \texttt{TerminalRole} is needed, in order to provide a common interface for other areas of the VEC. For example the Mating defines the connection between the sides of an inliner or between a harness connector and an ECU by using the \texttt{TerminalRole}. 
3.7 **Accessories**

Figure 18: Accessories

Accessories are parts that are not further specified in the VEC (e.g. caps or locks for connectors). Those components are marked with the `primaryPartType="Other"` and a `PartOrUsageRelatedSpecification` that can be used to define which type of "accessory" it is. Common part attributes can be defined with a `GeneralTechnicalPartSpecification`.

A relation between `PartVersion` and its accessories can be established with a `PartRelation` in a `GeneralTechnicalPartSpecification`. 
3.8 Grommets with Placement

Grommets have certain points (the `CableLeadThrough`) that are relevant for the placement of a grommet. Since currently the `CableLeadThrough` only specifies relevant information on the component side and not on the instance side, there is no corresponding subelement of the `GrommetRole`. The ability to place a `CableLeadThrough` on a specific point in the topology is covered by the generic mechanism of `PlacementPoints` & `PlacementPointReferences`.

3.9 Channels

`CableDucts` can fulfill have to relevant aspects. They can be connected with the harness (placement). This is specified with the blue classes. At the same time a `CableDuct` can have properties of a `Fixing` since it is often mounted to the vehicle body as well. This aspect is defined by an additional `FixingSpecification`.
4 Topology and Geometry

4.1 Placements

A Placement defines the way how a component is associated to the topology. The following sections contain examples about the different types of placements.

4.1.1 Simple WireProtection

The Figure above displays the placement of a simple wire protection. The PartOccurrence is placed with an OnWayPlacement via a PlacableElementRole. This means the placed component covers a linear area of the harness topology. The start and the end of this area is defined with two Locations. In the shown situation the StartLocation is a SegmentLocation, which means the start is somewhere in the middle of a TopologySegment. It is defined to be at 120mm measured from the EndNode of the TopologySegment. The EndLocation of the WireProtection is located on a TopologyNode with a NodeLocation. It is not valid to define Location with SegmentLocation, which could be also expressed by NodeLocations. This means for SegmentLocations an offset of 0 or equal to the segment length is illegal.
4.1.2 Large Area WireProtections

In some cases it is necessary to place a wire protection over a greater area of the topology, consisting of more than one TopologySegment (e.g. Tubes with a fixed length). For these cases the OnWayPlacement defines two locations for the start and the end and a path along which the wire protection is placed. The path is an ordered list of the segments from the start to the end. If a SegmentLocation is used for the start or the end the path must contain these segments as well.

For each TopologySegment the use of Start- and End-Node has no semantik relevance. The names are just used to make it possible to identify the corresponding TopologyNodes correctly e.g. when defining the anchor for a SegmentLocation.

Figure 22: Large Area WireProtections
4.1.3 Fixed Components (Single Location)

Fixed components are elements that are placed on a certain point in the topology, such as Connectors, Fixings and so on. These components are placed with an OnPointPlacement as shown in the example. If the Component has to be placed on a Node (e.g. a Connector) a NodeLocation is used. If the Component has to be placed on a Segment a SegmentLocation is used. The usage and constraints for the Locations are the same like the ones for OnWayPlacements.

Figure 23: Fixed Components (Single Location)
4.1.4 Fixed Components (Multiple Locations)

Some components, for example channels or a large connector with more than one segment connection point, may be placed on multiple positions in the Topology. For example a channel can have two or more reference points (e.g. the outlets) that must be associated to the different positions topology. In these cases an OnPointPlacement with more than one location is used. In order to identify which location places which point of the component (e.g. the outlets), a PlaceableElementRole can define PlacementPointReferences which are creating a relationship to the component description.

5 Connectivity

5.1 Contacting Specification

The contacting in the VEC defines the relationship between Cavities, WireEnds, Terminals and Seals. Since there are various types of contactings possible, the different types are not defined explicitly in the VEC. The VEC offers a quite generic structure (the Contacting), which should be able to support all the different possible types. This is necessary, because the different contacting types are driven by technical requirements and new contactings might emerge over the time. The downside of the generic structure is that the structural schema allows constellations that are not sensible from a technical point of view as well. The following sections show the different contacting types used today, and how they have to be implemented in the VEC.

Since the contacting can be used for different levels of abstraction (Product Definition or Electrological Wiring) only the “Role-Side” of the necessary objects is shown. Necessary PartOrUsageRelatedSpecifications, PartOccurrences, PartUsages and PartVersion are omitted.
5.1.1 Standard Contact

A standard Contacting is the most common case in a wiring harness. For a standard contact you have one wire end that has one terminal crimped on it, which is placed in one cavity. It exists in two variants, sealed and unsealed. The example displays the sealed variant, for the unsealed variant the CavitySeal and the CavityPlug have to be omitted.

The contacting is defined by a ContactPoint, contained in a ContactingSpecification. It is possible (and recommended) to define multiple ContactPoints in one ContactingSpecification. Usually there exists one ContactingSpecification per DocumentVersion in the scope. So for example if the VEC-File represents a 150%-Harness definition, then you will have one ContactingSpecification for the complete harness.

A ContactPoint is defined as a point of exactly one electrical potential, which means all conducting components related to the ContactPoint are short-circuit.

The ContactPoint defines the terminal that is used for the contacting. It is then split up into two parts, the side of the crimp of the terminal (represented by the WireMounting) and the side of the terminal, which is placed in the cavity (represented by the CavityMounting). Since the example is about a sealed standard contact, the WireMounting displayed references exactly one CavitySeal and one WireEnd, which means these two components are crimped together onto the terminal. On the other side the CavityMounting defines the Cavity in which the terminal will be placed. For a sealed environment it is necessary, that the Cavity is plugged with a CavityPlug, in case the Cavity is not occupied by a contacting. If the Cavity is occupied, the CavityMounting defines explicitly, which CavityPlugs are replaced by its existence.
5.1.2 Multi Crimp Contact

A Multicrimp is quite similar to the standard contact, with the difference that there is more than one wire crimped onto the terminal. Therefore the displayed example is quite the same. The differences are:

- There is no CavityPlug or CavitySeal, since it is not useful / possible from a technical point of view to seal a multicrimp.
- There are two (or more) WireEnds associated with the WireMounting.

For clarification of the example the two WireElementReferences reference their Signal. It is the same, since the two WireEnds are crimped onto one Terminal and therefore they are set to one single electrical potential. This is only displayed in the example in order to make it clear, what is meant by “A ContactPoint has one single electrical potential”. This is not a restriction of the VEC, since the development processes might need (or create) different signal names for the same electrical potential.
5.1.3 Ringterminal - Splice

The structure displayed in the example applies to ring terminals and splices as well. On the side of the wire it is the same as a multi crimp. The difference is that no cavity mounting is used, since a ring terminal / splice has no cavities.
5.1.4 Bridge Terminal

A bridge terminal is a terminal that has a wire crimped on it and which occupies more than one cavity (short-circuited). On the side of the wire it is the same as a standard contact. On the side of the cavities it simply references more than one cavity.

5.1.5 Coax Contact

The diagram displays the proper definition of a coax contacting. In the case of coax contact one single terminal is used, but two different electrical potentials are connected to it. Therefore two ContactPoints are required, because one ContactPoint can only be used for one electrical potential (see the definition of a ContactPoint).
Both ContactPoints reference the same occurrence of the terminal (TerminalRole) and use the Cavity. Each ConcatPoint mounts a single WireElement to the TerminalRole. In this example the two WireElements belong to the same multi-core wire.

In order to make the example more clearly, the next figure displays the definition of such a “coax-cavity” in an EEComponent.

5.1.6 Coax Cavity

The HousingComponent of an EEComponent defines on one hand the pins (electrological relevant information) in this HousingComponent and on the other hand a ConnectorHousingSpecification (the layout and design of the HousingComponent). The PinComponents are then positioned in the cavities. In the case of a coax contact, two PinComponents (the different electrical potentials) are placed in one cavity.
5.2 Mating Specification

The contacting defines in the VEC the relation of a terminal, a wire, a seal and a cavity in a connector on the harness side. The mating can be used to connect the harness side to another harness (in the case of an inliner) or to an ECU. The figure above shows a simplified example of the connection between an ECU (highlighted in yellow) and a wiring connection (highlighted in blue). The MatingPoint simply connects the two TerminalRoles on each side.

6 Complex Part Descriptions

This section is about the definition of Harnesses, Modules and Assemblies.
6.1 Module

The figure shows how a module can be defined in a 150% environment. A module basically consists of a number of PartOccurrences. In a 150%-Harness the PartOccurrences can be shared between modules. Therefore a single container is needed, which defines a PartOccurrences that belong to the Harness, independent from the Module. This is done by a CompositionSpecification. The PDM information of a module is stored in the PartVersion. The PartOccurrences belonging to the Module (the “Bill Of Material”) are defined by a PartStructureSpecification.
6.2 Harness

In the philosophy of the VEC a harness is quite the same as a module. A module is formed by a set of occurrences of components. A harness is formed by a set of occurrences of modules. This approach has the advantage that the same module can be used in different harnesses with for example different VariantConfigurations. The figure shows a simple configuration of a 150%-harness. The harness has a PartStructureSpecification, which defines the BOM of the Harness. This BOM contains the two PartOccurrences of the modules from the previous example. Each PartOccurrence can carry a VariantConfiguration. Since the two modules share a component, they are mutually exclusive (see the different VariantConfigurations).
6.3 Assemblies

Figure 34: Assemblies

The figure above displays the usage of assemblies in the VEC. Assemblies are more complex components, which are built out of a number of other components (e.g. a prebuild wire with connectors attached to it). There are multiple reasons, why the inner structure of an assembly is relevant, but the most important one is that the inner components are needed to describe the correct usage of the assembly in the harness. For example in the case of the prebuild wire, the connectors are needed to define their position in the topology and the wire is needed to define the routing of the assembly through the topology.

In the upper area of the figure (highlighted in yellow) the master data of the assembly is shown (for simplification it contains only one PartOccurrence “B”). When the assembly is used in a Harness it is instantiated (highlighted in blue). In the example the assembly is instantiated twice (PartOccurrence ASS1 & ASS2), since an assembly can be used multiple times in the same context. All subcomponents of the the assembly must be instantiated as well (PartOccurrence B1 & B2). These PartOccurrences carry a reference to the PartOccurrence in the Part Master Data they represent. The instantiated PartOccurrences are used to define the concrete usage of the Assembly. It is also possible, that the concrete usage has properties different to the represented
occurrence. The most common use case for this is the naming of the PartOccurrence. Another use case, which is not so obvious, is for example that a prebuild wire can have only one connector attached to it and the other side is left open. When the wire is used, it is cut to needed length and then contacted on the open side. In this case the wire length of the instantiated wire would be different to master data definition of the assembly.

7 External Mapping

7.1 Simple External Mapping

The Diagram shows a simple example for the usage of the external mapping mechanism. The elements highlighted in yellow represent the actual information described by this VEC instance. The elements highlighted in blue are defining the concrete mapping and the DocumentVersion highlighted in green represents the link to the mapped document (in this case a SVG-symbol).

The ExternalMapping element in this example defines that a representation of the referenced ConnectorHousingSpecification can be found in the SVG-symbol under the key "ID_27101123".

The actual content data of the VEC-file (highlighted in yellow) and the mapping information is separated into two different DocumentVersion elements. This means even though both information are contained in the same VEC-file, from the perspective of a versioning mechanism they are clearly separated.

8 Systems Schematic

The following section contains examples for the usage of different parts of the VEC required for the mapping of a specific use case, the “Systems Schematic".
8.1 Variant Management for ECUs

This example demonstrates how the variant management can be handled in the systems schematic on different levels of abstraction.

The top most element is the usage node. It defines an abstract position / function in the vehicle. In the example it is the back light on the left hand side (named "MX3"). This function can be realized by two different electrological variants (interfaces). These variants are represented by ComponentNodes. In the example there is one variant with two pins (MX3.1) and one variant with three pins (MX3.2). On a more concrete level these interfaces can be satisfied by one or more EE-components (alternatives). These EE-Components are defined by PartVersion with a EEComponentSpecification. In order to define restrictions a corresponding PartOccurrence with a VariantConfiguration can be defined.

The PartUsages in the example are needed for to reasons:

1. They serve as a container to group the different possible alternatives (“realizedPartUsage”).
2. It is necessary to declare one of the EEComponents as the representative of all alternatives of a variant. This is done by the reference between the PartUsage and the corresponding EEComponentSpecification.

Figure 36: Variant Management for ECUs
9 Packaging

9.1 Indexing of VEC Package

This example explains how more than one VEC file can be packaged together with external documents, for example symbols of the specified components. In this case the VEC shall be packed within an archive together with the external documents (according to the current published VEC recommendation) and an index file has to be provided.

The upper half of the diagram illustrates the file structure within the archive. In the root there is a 'index.vec' file that describes the content of the archive. The simplified content of this index file is illustrated in the lower half of the diagram.

For the example, the archive consists of following files:

- index.vec: Describes the content of the archive.
- A harness with the part number 4811 specified by a VEC-File (4811_a.vec) and a 2D SVG representation of the harness (4811_a.svg).
- A component description of connector housing (part number: 4711) specified with a VEC-File (4711_a.vec) and component symbol (to be used in the 2D-drawing) defined with a SVG-Symbol (4711_a.svg).

In the VEC (especially in the index.vec) a DocumentVersion object is created for each external document (see lower half of the diagram). This DocumentVersion object references the PartVersion to which it is related. Beside all meta information about the document, the attribute dataFormat of the DocumentVersion specifies the format of the external document as a MIME-Type. The attribute fileName is a path relative to VEC-File pointing to the external document in the archive.

### 9.2 External Installation Instructions

![Diagram of External Installation Instructions](image)

Figure 38: External Installation Instructions

The usage of file-based installation instructions is quite similar to the described approach for external documents. The FileBasedInstruction defines a pointer to the file packaged together with the VEC-file in the container and is referenced by the PartOccurrence.

The same effect could be achieved if a DocumentBasedInstruction is used, pointing to an external document (defined as described in the section before).

**Important:** The difference between the two approaches is that for the DocumentBasedInstruction a DocumentVersion is required. This means that the external file must be an official document with a document number, an appropriate versioning and so on. The FileBasedInstruction can point to any file needed. **It is not a valid approach to use the FileBasedInstruction, if the external file is a valid document.**
